Dynamic Edematous Response of the Human Heart to Myocardial Infarction
Implications for Assessing Myocardial Area at Risk and Salvage

BACKGROUND: Clinical protocols aimed to characterize the post–myocardial infarction (MI) heart by cardiac magnetic resonance (CMR) need to be standardized to take account of dynamic biological phenomena evolving early after the index ischemic event. Here, we evaluated the time course of edema reaction in patients with ST-segment–elevation MI by CMR and assessed its implications for myocardium-at-risk (MaR) quantification both in patients and in a large-animal model.

METHODS: A total of 16 patients with anterior ST-segment–elevation MI successfully treated by primary angioplasty and 16 matched controls were prospectively recruited. In total, 94 clinical CMR examinations were performed: patients with ST-segment–elevation MI were serially scanned (within the first 3 hours after reperfusion and at 1, 4, 7, and 40 days), and controls were scanned only once. T2 relaxation time in the myocardium (T2 mapping) and the extent of edema on T2-weighted short-tau triple inversion-recovery (ie, CMR-MaR) were evaluated at all time points. In the experimental study, 20 pigs underwent 40-minute ischemia/reperfusion followed by serial CMR examinations at 120 minutes and 1, 4, and 7 days after reperfusion. Reference MaR was assessed by contrast-multidetector computed tomography during the index coronary occlusion. Generalized linear mixed models were used to take account of repeated measurements.

RESULTS: In humans, T2 relaxation time in the ischemic myocardium declines significantly from early after reperfusion to 24 hours, and then increases up to day 4, reaching a plateau from which it decreases from day 7. Consequently, edema extent measured by T2-weighted short-tau triple inversion-recovery (CMR-MaR) varied with the timing of the CMR examination. These findings were confirmed in the experimental model by showing that only CMR-MaR values for day 4 and day 7 postreperfusion, coinciding with the deferred edema wave, were similar to values measured by reference contrast-multidetector computed tomography.

CONCLUSIONS: Post-MI edema in patients follows a bimodal pattern that affects CMR estimates of MaR. Dynamic changes in post–ST-segment–elevation MI edema highlight the need for standardization of CMR timing to retrospectively delineate MaR and quantify myocardial salvage. According to the present clinical and experimental data, a time window between days 4 and 7 post-MI seems a good compromise solution for standardization. Further studies are needed to study the effect of other factors on these variables.
Noninvasive tissue characterization by cardiac magnetic resonance (CMR) after myocardial infarction (MI) offers the possibility to evaluate the impact of interventions designed to preserve cardiac function and predict long-term remodeling.\(^1\) It has been postulated that an intense edematous reaction confined to the postischemic region appears early after MI and persists in a stable form for at least 1 week.\(^2,3\) On the basis of this assumption, the use of edema-sensitive T2-CMR sequences to delineate the spatial extent of post-MI edema was rapidly incorporated as an index of the original occluded coronary artery perfusion territory (myocardium at risk, MaR).\(^4,5\) Quantification of late gadolinium enhancement (LGE) and edema extent (assumed to delineate MaR) in the same imaging session has been extensively used to take account of the pathophysiology of the bimodal edematous phenomenon.

Circulation. 2017;136:1288–1300. DOI: 10.1161/CIRCULATIONAHA.116.025582
of metallic objects or devices incompatible with MRI. Patients were managed according to current clinical guidelines.\textsuperscript{14,15}

CMR examinations were performed within 3 hours of reperfusion (hyperacute reperfusion) and at 24 hours, 4 days, 7 days, and 40 days after reperfusion (Figure 1A). Normal T2 relaxation times (baseline) were obtained in 16 healthy age- and sex-matched volunteers. The study was approved by the hospital Ethics Committee, and all patients and volunteers gave written informed consent.

**CMR Protocol**

CMR examinations were conducted with a Philips 1.5-Tesla Achieva whole-body scanner (Philips Healthcare) equipped with a 16-element phased-array cardiac coil. At all time points, the imaging protocol included a standard segmented cine steady-state free-precession sequence to provide high-quality anatomic references; a T2-weighted short-tau triple inversion-recovery (T2W-STIR) sequence to assess the extent of edema and intramyocardial hemorrhage (IMH); and a T2-gradient-spin-echo mapping sequence to provide precise myocardial T2 relaxation time properties.\textsuperscript{16} On day 7 and day 40 CMR, LGE imaging was performed to assess infarct size and microvascular obstruction (MVO), using a T1-weighted inversion recovery turbo field echo sequence acquired 10 to 15 minutes after intravenous administration of 0.20 mmol gadobutrol contrast agent per kg body weight.

**CMR Analysis**

CMR images were analyzed using dedicated software (MR Extended Work Space 2.6, Philips Healthcare; and QMassMR 7.6, Medis) by 2 observers experienced in CMR analysis and blinded to time-point allocation and patient identification. T2 maps were analyzed by placing the region of interest at the transmural ischemic, infarcted (with or without including areas suggestive of IMH), salvage, and transmural remote areas in a midapical ventricular short-axis slice corresponding to the same anatomic level in all acquisitions to track T2 relaxation time changes over time.\textsuperscript{16,17} The extent of edema, expressed as a percentage of left ventricular (LV) mass (CMR-MaR), was initially identified by using the full width at half-maximum with subsequent manual correction and visual border delineation after tracing the endocardial and epicardial contours of T2W-STIR short-axis images.\textsuperscript{18} Hypointense areas within the edematous zone, corresponding to IMH, were included within the edematous region.\textsuperscript{19,20} In addition, IMH area was calculated by manual delineation of the hypointense areas on T2W images\textsuperscript{19} and expressed as a percentage of LV mass.

IS, expressed as a percentage of LV mass, was defined according to the extent of LGE after manually tracing the endocardial and epicardial contours on T1-weighted inversion recovery turbo field echo short-axis images. Abnormal areas were defined using the full width at half-maximum, with manual correction if needed. Hypointense black areas within the necrotic zone, corresponding to MVO, were included within the necrotic area.\textsuperscript{19,20} In addition, the size of the MVO area was calculated by manual delineation of

![Figure 1. Study design.](http://ahajournals.org)

**A.** Clinical study design. Twenty-two consecutive anterior patients with STEMI fulfilling the inclusion criteria were assessed for eligibility: 3 patients refused to participate; 1 patient experienced anxiety and a claustrophobic reaction requiring premature termination of the first CMR; 1 patient felt sick with vomiting before the first CMR, which could not be performed; and 1 patient had a failed CMR study because of frequent episodes of premature ventricular contraction and nonsustained ventricular tachycardia during the scan. The clinical study population thus included 16 consecutive hemodynamically stable patients with anterior STEMI reperfused by primary percutaneous coronary intervention. CMR examinations including T2-weighted short-tau triple inversion-recovery and T2-gradient-spin-echo mapping sequences were per protocol scheduled at the following times after reperfusion: within the first 3 hours and at 24 hours, 4 days, 7 days, and 40 days. To take account of baseline values, myocardial T2 relaxation time was measured in 16 healthy age- and sex-matched volunteers.**

**B.** Experimental study design. The study population comprised 20 pigs weighing 30 to 40 kg that underwent closed-chest 40 minutes reperfused acute anterior myocardial infarction. These pigs were euthanized at 120 minutes (n=5), 24 hours (n=5), 4 days (n=5), and 7 days (n=5) after myocardial infarction. Arterial enhanced multidetector computed tomography was performed during coronary occlusion in all pigs as a reference standard for measuring the myocardial area at risk. CMR scans, including T2-weighted short-tau triple inversion-recovery, T2 mapping, and late gadolinium enhancement imaging, were performed at every follow-up stage until euthanization. CMR indicates cardiac magnetic resonance; I/R, ischemia/reperfusion; MDCT, multidetector computed tomography; PCI, percutaneous coronary intervention; and STEMI, ST-segment-elevation myocardial infarction.
the hypointense areas on LGE images and expressed as a percentage of LV mass.

Detailed information about CMR imaging protocol and parameters, and imaging analysis is presented in the online-only Data Supplement Methods.

Experimental Study

Design and MI Procedure

The study was approved by Institutional and Regional Animal Research Committees.

To study the impact of the dynamic edematous response on post-MI CMR time profile measures of MaR, IS, and salvaged myocardium, a group of 20 pigs underwent closed-chest reperfused MI by the percutaneous catheter-based technique, with 40-minute angioplasty-balloon occlusion of the mid left anterior descending coronary artery, followed by balloon deflation and reestablishment of blood flow (Figure 1B). These pigs were euthanized at 120 minutes (n=5), 24 hours (n=5), 4 days (n=5), or 7 days (n=5) after ischemia-reperfusion (I/R). In all pigs, arterial enhanced multidetector computed tomography (MDCT) was performed during the index coronary occlusion, between minute 10 and minute 20 of ischemia, to delineate the reference MaR (hypoperfused region during coronary occlusion). Comprehensive CMR scans were performed at every follow-up stage until euthanization (ie, animals euthanized on day 7 underwent baseline, 120 minutes, 24 hours, day4, and day7 CMR examinations).

Full methods can be found in the online-only Data Supplement Appendix.

Arterial Enhanced MDCT Protocol and Analysis

All MDCT studies were performed on a 64-slice CT scanner (Brilliance CT 64, Philips Healthcare) after intravenous administration of 60 mL of 400 mgI/mL iomeprol (Iomeron 400, Bracco Imaging). MDCT images were analyzed using dedicated software (MR Extended Work Space 2.6, Philips Healthcare). MaR and remote areas were visually identified based on contrast enhancement differences, manually delineated, and expressed as a percentage of LV area.

CMR Protocol and Analysis

CMR examinations were conducted with a Philips 3-Tesla Achieva Tx whole body scanner (Philips Healthcare) equipped with a 32-element phased-array cardiac coil. The imaging protocol included an steady-state free-precession sequence to provide high-quality anatomic references, and assessment of LV mass and wall thickness; a T2W-STIR sequence to assess the extent of edema and IMH; a T2-gradient-echo mapping sequence; and a T1-weighted inversion recovery turbo field echo sequence to assess IS and MVO. CMR images were similarly analyzed using dedicated software (MR Extended Work Space 2.6, Philips Healthcare; and QMassMR 7.6, Medis) by 2 observers experienced in CMR analysis and blinded to group allocation.

Detailed information about MDCT and CMR imaging protocol and parameters, and imaging analysis, can be found in the online-only Data Supplement Methods.

Statistical Analysis

In the clinical study, the sample size calculation to detect a difference in T2 relaxation time in the ischemic myocardium between examination time points after STEMI was prespecified by using the user-written command power (Stata 12.0). A sample size of 16 patients was determined on the basis of our previous experimental results, a 95% confidence level, a statistical power of 80%, a conservative significant mean difference to detect of 15 ms in T2, a SD of 12, and multiple pairwise comparisons between time points.

Normal distribution of each data subset was checked by using graphical methods and a Shapiro-Wilk test. The Leven test was performed to check the homogeneity of variances. For quantitative variables, data are expressed as mean±SD. For categorical variables, data are expressed as frequencies and percentages. To take account of repeated measures, generalized linear mixed models were conducted to analyze the time course of T2 relaxation time, CMR-MaR, IMH, MVO, IS, and salvaged myocardium. Models evaluating the time course of T2 or CMR-MaR were further adjusted by extent of hemorrhage, including the amount of IMH expressed as a percentage of the LV as a covariate, given that this parameter is known to affect T2. Given the hypothesis-driven nature of the study, comparisons among different time points were planned in advance. Nonetheless, P value was adjusted for multiple comparisons by using the Hochberg method.

All statistical analyses were performed with Stata v12.0 (StataCorp).

RESULTS

Clinical Study

General Characteristics of the Population

Clinical characteristics of the study population are summarized in Table 1. Serial CMR was performed with informed consent in 16 consecutive patients with anterior STEMI fulfilling the inclusion criteria (mean age 58.8±14.5 years, 14 [87.5%] male) and successfully treated by primary percutaneous coronary intervention. A total of 94 CMR examinations were performed: the 16 healthy volunteers were scanned once, and the 16 patients with STEMI were scanned at 2.2±0.5 hours, 24.8±1.8 hours, 3.8±0.4 days, 6.8±0.6 days, and 41.7±4.3 days after reperfusion. In all patients, the first CMR scan was performed within the first 3 hours (90–180 minutes) after primary percutaneous coronary intervention. The timing for the initial CMR scan (around the peak of reperfusion-related wave of edema) was identified before in a dedicated separate group of 5 pigs undergoing serial CMR scans every 20 minutes during the 6 hours following reperfusion (see online-only Data Supplement Methods and Results, and online-only Data Supplement Figures I and II). Evaluative T2-mapping and T2W-STIR data were available in 100% of CMR scans performed. Information on vital status was available for all participants.
Edema Time Course in Patients With STEMI

T2 Relaxation Time

Mean myocardial T2 relaxation times in the 16 healthy volunteers (mean age 59.3±17.7 years, 12 [75%] male) were 53.1±4.1 ms and 51.1±4.5 ms for the midapical anteroseptal and posterolateral LV walls, respectively. In comparison with these values, hyperacute reperfusion in patients with STEMI (≤3 hours) was associated with significantly longer T2 relaxation times in the ischemic area (Figure 2A and 2B). T2 relaxation time in patients with STEMI showed a systematic and significant decrease at 24 hours post-MI. This was followed by a rebound increase, with T2 relaxation times on day 4 postreperfusion reaching values similar to those observed during early reperfusion. Thereafter, T2 relaxation time progressively decreased, with values on day 40 similar to those observed at 24 hours. Similar results were obtained after adjusting T2 for the amount of IMH (online-only Data Supplement Table I). During the first week after MI, T2 relaxation time in the remote myocardium showed a linear trend toward a progressive increase, albeit slight. T2 relaxation times in the ischemic and remote myocardium at different postreperfusion time points are summarized in Table 2. T2 relaxation time was longer in the transmural ischemic myocardium than in the remote myocardium at all time points evaluated. However, the differences observed at 24 hours and 40 days, albeit statistically significant, were of small magnitude and resulted in a wide overlapping of myocardial T2 values within ischemic and remote areas (Figure 2C). Individual trajectories for T2 relaxation time in the ischemic myocardium of STEMI patients are shown in online-only Data Supplement Figure III.

Extent of Edema (CMR-MaR)

The edematous area delineated by T2W-STIR sequences was similar in CMR scans performed at hyperacute reperfusion (≤3 hours) and on day 4 and day 7 (Figure 3). Conversely, the area of edema was significantly smaller at 24 hours postreperfusion. On day 40 post-MI, the area of edema was comparable to that seen at 24 hours. This time-course pattern for edema resembles that observed for T2 relaxation time, and similar results were obtained after adjusting the area of edema for the amount of IMH evaluated by T2W-STIR (online-only Data Supplement Table II). Edematous area at different postreperfusion time points is summarized in Table 2. Individual patient trajectories for area of edema measurements are shown in online-only Data Supplement Figure IV.

Experimental Study

Dynamics of CMR-MaR After Reperfused MI in Comparison With the Reference Standard

CMR-measured MaR values at different times after reperfusion in pigs are summarized in Table 3 and online-only Data Supplement Table III. Mean MaR as assessed by the MDCT reference method was 30.5±5.0% of the LV. Because of the initial swelling of the ischemic myocardium (online-only Data Supplement Table IV), CMR-measured MaR as delineated by T2W-STIR sequence was significantly higher than MaR measured by MDCT at early reperfusion (Figure 4A and 4B). Coinciding with the dissipation of the first edema wave,10 MaR was strikingly underestimated by CMR at 24 hours postreperfusion. Conversely, CMR-estimated MaR values for day 4 and day 7 postreperfusion, coinciding with the deferred edema wave,10 were similar to values measured by MDCT (ie, no overestimation or underestimation). The dynamics of CMR-measured MaR resembled the time course for myocardial T2 relaxation time and water content in the ischemic area.10
Dynamics of CMR-Measured IS, Myocardial Salvage, IMH, and MVO After Reperfused MI

CMR-measured IS and myocardial salvage in pigs are summarized in Table 3 and online-only Data Supplement Table III. A progressive reduction of IS was observed during the first week after I/R (Figure 4C and 4D). Matching the temporal variations in CMR-MaR, CMR-estimated myocardial salvage quantification [(MaR-IS)/MaR, %] also changed dynamically during the first week after I/R (online-only Data Supplement Figure V).

CMR-estimated IMH and MVO are summarized in online-only Data Supplement Table V. IMH was apparent at 24 hours and peaked on day 4 post-I/R; in contrast, MVO was apparent at 120 minutes after reperfusion, peaking on day 1 post-I/R and progressively decreasing thereafter. The dynamics of CMR-estimated
IMH are consistent with histologically evaluated IMH in the same model previously reported.11

**DISCUSSION**

**First Demonstration of the Postinfarction Bimodal Edema Reaction in the Human Heart**

This is the first comprehensive evaluation of patients with STEMI by serial CMR to include the hyperacute postreperfusion period (the first 3 hours). CMR scans timing was designed as per the protocol of our previous experimental studies, in which we demonstrated the existence of bimodal post-MI edema in pigs.10,11

The main finding of the present clinical study is that, contrary to the accepted view, myocardial edema in the ischemic area after MI in humans is not stable, but rather follows a systematic bimodal pattern. An initial wave of edema appears abruptly very early after reperfusion, but it is significantly attenuated by 24 hours. This is followed by a second (deferred) wave of edema several days after reperfusion reaching a plateau ≈4 to 7 days after MI.

**The Initial Wave of Edema**

To select the optimal timing for the first CMR scan in STEMI patients, we first analyzed the dynamics of the initial wave of edema in a series of 5 pigs; serial CMR scans were performed every 20 minutes until the reperfusion-related edema wave faded. It is interesting to note that this initial wave of edema peaked very early, being significantly attenuated within a few hours after MI: at 180 minutes after reperfusion, the edema had declined by ≈50% from its maximum. In agreement with CMR data, quantification of myocardial water content and histological analysis at 6 hours after MI revealed partial resolution of the massive interstitial edema seen earlier after reperfusion (see online-only Data Supplement Results).11 On the basis of these results in pigs, we decided to perform the first CMR scan in patients within a narrow 3-hour time window after primary percutaneous coronary intervention to be able to detect the noon of the initial wave of edema.

**Controversy on the Bimodal Postinfarction Edema Occurrence in Humans**

The recent demonstration of bimodal edema in the postischemic myocardium in pigs10,11 has generated intense discussion in the cardiac imaging field.6,22–28 Whether this phenomenon occurs in humans has been explored in 2 recent studies. Carrick and colleagues13 performed a longitudinal assessment of IMH and edema in 30 patients with STEMI, concluding that “myocardial edema has a unimodal time course.” This population was more heterogeneous than the population examined here: 20% had an open artery on angiography (TIMI coronary flow grade 2–3) and only 30% had an anterior MI, whereas all patients in our study had an anterior infarction with an occluded artery on angiography. These factors might affect edema dynamics and visualization.11,18 In addition, patients in the Carrick et al study underwent 3 CMR examinations within the first 10 days after MI, at 8.6±3.1 hours, 2.9±1.5 days, and 9.6±2.3 days.13 It is important to note that the first of these examinations was performed between 4 and 12 hours after reperfusion, which, according to the experimental data we present here, is after the dissipation of the first edema wave. Indeed, the T2 values in the infarcted zone reported for the first CMR examination in Carrick et al are similar to those observed in the second scan in our clinical study, performed 24 hours after MI.

In the second report, Nordlund et al12 retrospectively analyzed pooled data from 3 studies assessing the MaR by qualitative CMR, concluding that no bimodal edema pattern was apparent. However, most patients in the evaluated studies underwent a single CMR scan at disparate times to from each other, and there were no systematic serial examinations. It is important to note that no CMR scans were performed on day 0, and very few were performed on day 1 after MI. Moreover, no quantitative parametric T2 mapping was performed, despite this technique being demonstrated to improve detection and quantification of myocardial edema.29

Unlike these recent reports, our study was specifically designed to provide insight into the existence of bimodal edema in patients with MI by mimicking time points and CMR sequences performed in the previous experimental studies.10,11

Implications of the Bimodal Edema Phenomenon for Quantifying MaR and Salvage

On the basis of an assumed stable edematous reaction lasting for several days after MI and despite recent controversy,30,31 T2-CMR sequences have been widely used to retrospectively quantify the MaR by qualitative CMR, concluding that no bimodal edema pattern was apparent. However, most patients in the evaluated studies underwent a single CMR scan at disparate times to from each other, and there were no systematic serial examinations. It is important to note that no CMR scans were performed on day 0, and very few were performed on day 1 after MI. Moreover, no quantitative parametric T2 mapping was performed, despite this technique being demonstrated to improve detection and quantification of myocardial edema.29

In the present clinical study, we show that T2 relaxation time in the ischemic region changes systematically with the post-MI timing of the examination. In parallel, we confirmed significant variation in the extent of the MaR as measured by T2W-STIR. Consistent with the drop in T2 relaxation time at 1 day post-MI, T2W-estimated MaR at this time point was significantly lower than values obtained before and subsequently.

We experimentally confirmed clinical findings by accomplishing a comprehensive CMR serial imaging study in 20 pigs subjected to reperfused MI. Remarkably, we included prereperfusion MDCT imaging as a reference for the assessment of MaR,21 which otherwise we con-

Data are presented as mean (SD). T2 maps were analyzed by placing regions of interests at the transmural ischemic, infarcted (with or without including areas suggestive of intramyocardial hemorrhage), salvage, and transmural remote areas in a midapical ventricular short-axis slice corresponding to the same anatomic level in all acquisitions to track T2 relaxation time changes over time. The different myocardial states were initially defined by the localization relative to late gadolinium enhancement. The parallel courses of T2 and CMR-MaR fluctuations observed in the clinical and experimental settings strengthen the message of the present study. Thus, our data suggest that between day 4 and day 7 would be a good compromise solution for the delineation of theoretical MaR.

Nevertheless, our results highlight the need for caution in interpreting CMR of the post-MI heart. In the clinical study, 3 of the 16 patients with STEMI showed more limited changes in T2 and extent of edema (see online-only Data Supplement Figures III and IV). Remarkably, these 3 patients were older and showed significantly smaller infarcts and less extent of IMH and MVO, and greater myocardial salvage areas despite having longer intervals between symptom onset to reperfusion (data not shown). We speculate that there might be several factors affecting the dynamics of the bimodal edematous reaction such as the existence of preformed collateral circulation, episodes of spontaneous reperfusion/reocclusion during ischemia duration, or the presence of specific comorbidities. The impossibility of controlling these aspects in the clinical scenario considered unethical to perform in patients with STEMI. In the experimental study, our results show that, because of the bimodal pattern of post-IR edema formation, the extent of MaR delineated by T2-CMR varies during the first week after IR. Specifically, the edema-sensitive T2W-STIR CMR sequence overestimates MaR in comparison with MDCT at early time points (120 minutes) after reperfusion, which is in agreement with previous reports. This overestimate is mainly driven by swelling after reperfusion, which is in agreement with previous reports. Moreover, the more severe ischemic process in the porcine myocardium in the presence of poor collateral circulation, among other reasons, could influence the magnification of this phenomenon. However, the parallel courses of T2 and CMR-MaR fluctuations observed in the clinical and experimental settings strengthen the message of the present study. Thus, our data suggest that between day 4 and day 7 would be a good compromise solution for the delineation of theoretical MaR.
and the limited sample size preclude any definitive conclusion in this regard, but further studies are warranted.

In comparison with T2W-STIR, parametric T2 mapping might improve the detection and quantification of myocardial edema; however, it is unlikely to alter the dynamic pattern of post-MI edema that is attributable to pathophysiological phenomena. The deferred edema wave is related to the post-MI healing process, and therefore interventions that protect the myocardium could affect the dynamics of edema, and thus bias MaR estimation. This idea is supported by recent suggestions that the extent of edema can be affected by the degree of damage or exposure to infarct-limiting interventions. However, patients in these studies received 1 CMR examination at a single time point, which was not the same for all. Therefore, a dedicated study would be needed to provide evidence to support this hypothesis.

**IMH Is Not the Main Mechanism Underlying Bimodal Post-MI Edema**

In the clinical study, IMH, assessed by T2W-CMR, peaked around day 4 after reperfusion. This finding is in agreement with the present experimental CMR data and histologically validated data from our previous pig study. Given that T2 can be affected by hemorrhage, some authors have argued that the bimodal post-MI T2-CMR pattern could be explained entirely by the destructive paramagnetic effects of deoxyhemoglobin, rather than by a real fluctuation of tissue water content. However, if hemorrhage was the sole explanation for the bimodal T2 pattern, it would be difficult to understand why T2 (both in the pig model and in the present clinical study) and water content (in the pig model) increased to day 4, coinciding with the maximum extent of hemorrhage. In fact, in the clinical study, we observed no significant influence of IMH on T2 relaxation time or area of edema delineation. The finding that infarcted (either with or without IMH areas) and salvaged myocardium displayed the same bimodal pattern strengthen our results. In line with our data, Carrick et al found small differences in T2 (<5 ms) between patients with and without hemorrhage, whereas

Data are presented as mean (SD). CMR data for each time point correspond to pooled data from all animals undergoing 40 minutes ischemia/reperfusion. The extent of myocardium at risk was assessed by MDCT reference during coronary occlusion in all animals (MDCT-MaR). MDCT-MaR as assessed during the index coronary occlusion was 30.5±5.0%, 29.6±4.7%, 29.1±3.9%, and 28.3±4.3% of left ventricle; for pigs followed up to 120 minutes (n=20), 24 hours (n=15), 4 days (n=10), and 7 days (n=5) after reperfusion. Myocardial salvage as assessed by MDCT/CMR [(MDCT MaR – CMR Infarct Size) / MDCT MaR, %] in each of these groups was –50.6±24.4% at 120 minutes, –20.4±16.9% at 24 hours, –4.8±17.1% at 4 days, and 9.1±19.9% at 7 days after reperfusion, respectively. Note that MDCT was performed in all pigs only once (during the index ischemic event). Online-only Data Supplement Table III shows all individual data from animals euthanized at each time point.

CMR indicates cardiac magnetic resonance; MaR, myocardium at risk; and MDCT, multisector computed tomography.
Hammer-Hansen et al.\textsuperscript{17} found that T2 relaxation time differed in the infarcted and salvaged myocardium, and both were significantly longer than remote in the postreperfused dog heart. It is interesting to note that the later study followed animals at 4 and 48 hours after MI with results indicating a partial resolution of edema in the first 48 hours after reperfusion.\textsuperscript{17,26} Nevertheless, hemorrhage might exert some influence on T2 relaxation time, as we previously conceded.\textsuperscript{10,11,16,23,24}

**Dynamics of Infarct Size Over the First Week After MI**

Consistent with previous observations,\textsuperscript{3,37,38} our experimental data show a progressive decrease of CMR-based IS. The substantial swelling of the early postreperfused myocardium might explain the large IS detected in our experimental study 120 minutes after reperfusion. The early period after reperfusion is associated with significant transient expansion of extracellular volume\textsuperscript{11,38}; gadolinium gets trapped in this expanded extracellular volume, but when extracellular volume recedes, gadolinium no longer stays in this area. In this interpretation, acutely detected LGE does not necessarily equate to irreversible injury and may severely distort estimates of salvaged myocardium. These data highlight the importance of performing CMR infarct imaging within a consistently defined and narrow time frame, preferably at the end of the first week, when using IS as an end point in clinical trials during the acute post-MI period.

**Chronotherapeutic Approaches**

New treatments demonstrating significant promise in preclinical experiments frequently produce no benefits in clinical trials,\textsuperscript{1,39} and the present results hint that timing of intervention might be a key determinant of this mismatch.\textsuperscript{40–43} We believe the discovery of the bimodal nature of post-MI edema will help in the design and new therapies for reducing infarct size and post-MI LV dysfunction.

In summary, we present the first demonstration that myocardial edema after MI is not stable in patients but instead follows a bimodal pattern, confirming recent experimental findings in pigs. The identification of such a pattern has important biological, diagnostic, prognostic, and therapeutic implications, and opens a route to further exploration of factors influencing this phenomenon. Remarkably, this bimodal edematous response after MI has a major impact on CMR-MaR, and consequently, myocardial salvage quantification given that measures of edema are greatly influenced by the timing of post-MI imaging.

**LIMITATIONS**

Only patients with anterior STEMI were recruited to the clinical study. The reasons for this choice include the...
CONCLUSIONS

Contrary to the accepted view, the post-MI edematous reaction in patients is not stable, but follows a bimodal pattern. The initial edema wave appears early on reperfusion and dissipates by 24 hours. The deferred edema wave emerges thereafter and reaches a plateau lasting from approximately day 4 to day 7 postreperfusion. Consequently, the MaR as measured by T2W-CMR changes dynamically according to timing of the CMR examination. Timing of CMR after MI for assessing MaR and salvaged myocardium needs to be standardized. According to the data presented, a time frame between day 4 and day 7 after reperfusion seems a good compromise solution although some other factors might affect these variables.

ACKNOWLEDGMENTS

The authors are greatly indebted to G. J. Lopez-Martin and Mª J. García-Sánchez for image acquisition in pigs and patient recruitment, respectively, and to the Cardiology Department at Hospital Universitario de Salamanca for patient recruitment and care. The authors thank T. Córdoba, O. Sanz, E. Fernández, and other members of the CNIC animal facility and farm for outstanding animal care and support. S. Bartlett (CNIC) provided English editing.

SOURCES OF FUNDING

This study was partially supported by a competitive grant from the Spanish Society of Cardiology (Proyectos de Investigación Traslacional en Cardiología de la Sociedad Española de Cardiología 2015, for the project Caracterización tisular miocárdica con resonancia magnética en pacientes tras infarto agudo de mioCardio con elevación de ST sometidos a angioplastia Coronaria primaria. Estudio SURF-CNIC), by a competitive grant from the Carlos III Institute of Health-Fondo de Investigación Sanitaria- and the European Regional Development Fund (ERDF/FEADER) (P10/02268 and P113/01979), the Spanish Ministry of economy, industry, and competitiveness (MEIC) and ERDF/FEADER SAF2013-49663-EXP. Dr Fernández-Jiménez holds a FICNIC fellowship from the Fundación Jesús Serra, the Fundación Interhospitalaria de Investigación Cardiovascular, and the Centro Nacional de Investigaciones Cardiovasculares Carlos III (CNIC), and Dr Agüero is a FP7-PEOPLE-2013-ITN.
Cardionext fellow. This study forms part of a Master Research Agreement between the CNIC and Philips Healthcare, and is part of a bilateral research program between Hospital de Salamanca Cardiology Department and the CNIC. This research program is part of an institutional agreement between FISI-Fundación Jiménez Díaz and CNIC. The CNIC is supported by the MEIC and the Pro CNIC Foundation, and is a Severo Ochoa Center of Excellence (MEIC award SEV-2015-0505).

DISCLOSURES
Dr Sánchez-González is a Philips Healthcare employee. The other authors declare no conflict of interest.
